Chapter 1

Using simLexis

1.1 Introduction

This vignette explains the machinery behind simulation of life histories through multistate models implemented in simLexis. In simLexis transition rates are allowed to depend on multiple time scales, including timescales defined as time since entry to a particular state (duration). This therefore also covers the case where time at entry into a state is an explanatory variable for the rates, since time at entry is merely time minus duration. Thus, the set-up here goes beyond Markov- and semi-Markov-models, and brings simulation based estimation of state-occupancy probabilities into the realm of realistic multistate models.

The basic idea is to simulate a new Lexis object [3, 1] as defined in the Epi package for R, based on 1) a multistate model defined by its states and the transition rates between them and 2) an initial population of individuals.

Thus the output will be a Lexis object describing the transitions of a predefined set of persons through a multistate model. Therefore, if persons starting are defined to be identical at start, then calculation of the probability of being in a particular state at a given time boils down to a simple enumeration of the persons in a particular state. Bar of course the (binomial) simulation error, but this can be brought down by simulation a sufficiently large number of persons.

An observed Lexis object with follow-up of persons through a number of states will normally be the basis for estimation of transition rates between states, and thus will contains all information about covariates determining the occurrence rates, in particular the *timescales* [2]. Hence, the natural input to simulation from an estimated multistate model will be an object of the same structure as the original observed. Since transitions and times are what is simulated, any values of lex.Xst and lex.dur in the input object will of course be ignored.

This first chapter of this vignette shows by an example how to use the function simLexis and display the results. The subsequent chapter discusses in more detail how the simulation machinery is implemented and is not needed for the practical use of simLexis.

1.2 simLexis in practice

This section is largely a commented walk-trough of the example from the help-page of simLexis, with a larger number of simulated persons in order to minimize the pure

simulation variation. When we want to simulate transition times through a multistate model where transition rates may depend on time since entry to the current or a previous state, it is essential that we have a machinery to keep track of the transition time on *all* time scales, as well as a mechanism that can initiate a new time scale to 0 when a transition occurs to a state where we shall use time since entry as determinant of exit rates from that state.

1.2.1 Simulation in a multistate model

Input for simulation of a single trajectory through a multistate model is a representation of the *current status* of a person, so it can basically be represented by a Lexis object where lex.dur and lex.Xst are ignored, since there is no follow-up (yet). The object that we supply to the simulation function must therefore contain information about all timescales of interest and which one of these that are defined as time since entry into a new state. This information is assumed to be in the attributes time.scale and time.since respectively. We shall call such an object as preLexis object.

Thus there are two main arguments to a function to simulate from a multistate model which is represented in a (pre-)Lexis object:

- 1. A (pre-)Lexis object representing the initial states and covariates of the population to be simulated. This has to have the same structure as the original Lexis object representing the multistate model. Except that values for lex.Xst and lex.dur are not required (since these are the quantities that will be simulated).
- 2. A transition object, representing the transition intensities between states. This is a list of lists of intensity representations. As an intensity representation we mean a function that for given a preLexis object produces estimates of the transition intensities at a set of supplied times since entry.

The names of the elements (which are lists) of the transition object will be names of the *transient* states, that is the states *from* which a transition can occur. The names of the elements of each of these lists are the names of states *to* which transitions can occur (which may be either transient or absorbing states).

If the transition object is called Tr then TR\$From1\$To2 (or Tr[["From1"]][["To2"]]) will represent the transition intensity from state "From1" to the state "To2".

Currently, these entries in the transition object must be glm objects, representing Poisson models for the transitions. These will normally be estimated using a time-split data-set, but it is really immaterial how they came about.

In addition to these two input items, there will be a couple of tuning parameters, which we will seek to give sensible defaults.

The output of the function will simply be a Lexis object with simulated transitions between states. This will be the basis for deriving sensible statistics from the Lexis object—see next section.

We start by loading the Epi package:

```
> options( width=90 )
> library( Epi )
> print( sessionInfo(), l=F )
```

```

1.3 Setting up a Lexis object

As an example we will use the DMlate dataset from the Epi package; it is a dataset simulated to resemble a random sample of 10,000 patients from the Danish National Diabetes Register. First we load the diabetes data and set up a simple illness-death model:

This is just data for a simple survival model with states "DM" and "Dead". Now we cut the follow-up at insulin start, which for the majority of patients (T2D) is a clinical indicator of deterioration of disease regulation. We therefore also introduce a new timescale, and split the non-precursor states, so that we can address the question of ever having been on insulin:

```
> dmi <- cutLexis( dml, cut = dml$doins,
                         pre = "DM"
+
                   new.state = "Ins"
                   new.scale = "t.Ins"
                split.states = TRUE )
 summary( dmi )
Transitions:
From DM Ins Dead Dead(Ins) Records: Events: Risk time:
                                                                  Persons:

```

We can show how many person-years we have and show the number of transitions and transition rates (per 1000), using the boxes.Lexis function to display the states and the number of transitions between them:

```
> boxes( dmi, boxpos=list(x=c(20,20,80,80),
+ y=c(80,20,80,20)),scale.R=1000 )
```

1.4 Analysis of rates

In the Lexis object (a data frame) each person is represented by one record for each transient state he occupies, thus in this case either 1 or 2 records, those who have a recorded time both without and with insulin have two records.

In order to be able to fit Poisson models with occurrence rates varying by the different time-scales, we split the follow-up in 6-month intervals for modeling:

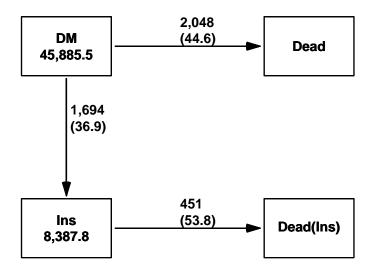

Figure 1.1: Data overview for the dmi dataset. Number in the boxes are person-years, and numbers on the arrows are no. of transitions and rates (transition intensities) per 1000 PY.

```
> Si <- splitLexis( dmi, 0:30/2, "DMdur" )</pre>
> dim( Si )
[1] 115370
               15
> print( subset( Si, lex.id==97 )[,1:10], digits=6 )

```

Note that when we split the follow-up each person's follow up now consists of many records, each with the *current* values of the timescales at the start of the interval represented by the record. In the modelling we must necessarily assume that the rates are constant within each 6-month interval, but the *size* of these rates we model as smooth functions of the time scales (that is the values at the beginning of each interval).

The approach that is often used in epidemiology with attaching one parameter to each intervals is not feasible when more than one time scale is used, because intervals are not classified the same way on all timescales.¹

We shall use natural splines (restricted cubic splines) for the analysis of rates, and hence we must allocate knots for the splines. This is done for each of the time-scales, and separately for the states "DM" and "Ins". We place the knots so that the number of events is the same between each pair of knots, but only half of this beyond each of the boundary knots:

```
> nk <- 5
> ( ai.kn <- with( subset(Si,lex.Xst=="Ins"),</pre>
                   quantile(Age+lex.dur, probs=(1:nk-0.5)/nk))
     10%
              30%
                       50%
                                 70%
                                          90%
23.75455 45.27279 56.62919 65.47851 77.50000
> ( ad.kn <- with( subset(Si,lex.Xst=="Dead"),</pre>
                   quantile( Age+lex.dur , probs=(1:nk-0.5)/nk ) )
     10%
              30%
                       50%
                                 70%

 1.0
```

We now fit Poisson models to transition rates, using the wrapper Ns from the Epi package to simplify the specification of the rates:

```
> library( splines )
> DM.Ins <- glm( (lex.Xst=="Ins") ~ Ns( Age , knots=ai.kn ) +
                                  Ns( DMdur, knots=di.kn ) +
                                  I(Per-2000) + sex,
                family=poisson, offset=log(lex.dur),
                data = subset(Si,lex.Cst=="DM") )
                                  ~ Ns( Age , knots=ad.kn ) +
Ns( DMdur, knots=dd.kn ) +
 DM.Dead <- glm( (lex.Xst=="Dead")</pre>
                                    I(Per-2000) + sex,
                family=poisson, offset=log(lex.dur),
                data = subset(Si,lex.Cst=="DM") )

                data = subset(Si,lex.Cst=="Ins") )
```

1.4.1 Proportionality of mortality rates

Note that we have made separate models for the three transitions, there is no assumption of proportionality between the mortality rates from DM and Ins.

However, there is nothing that prevents us from testing this assumption; we can just fit a model for the mortality rates in the entire data frame Si, and compare the deviance from this with the sum of the deviances from the separate models:

```
> with(Si, table(lex.Cst))
lex.Cst
       DM
                          Dead Dead(Ins)
                 Ins
    97039
              18331
                             \cap
> All.Dead <- glm( (lex.Xst %in% c("Dead(Ins)", "Dead")) </pre>
                                              Ns( Age , knots=ad.kn ) +
                                              Ns( DMdur, knots=dd.kn ) +
                                              lex.Cst +
                                              I(Per-2000) + sex,
                  family=poisson, offset=log(lex.dur),
                  data = Si )
> round( ci.exp( All.Dead ), 3 )
```

```

```

From these parameter values we would in a simple setting just claim that start of insulin-treatment was associated with a slightly more than doubling of mortality.

We can compare the fit of this model with the fit of the separate models for the two mortality rates, by adding up the deviances and d.f. from these:

```
> what <- c("null.deviance", "df.null", "deviance", "df.residual")</pre>
> ( rD <- unlist( DM.Dead[what] ) )</pre>
null.deviance
                     df.null
                                   deviance
                                              df.residual
     19957.95
                    97038.00
                                   17853.93
                                                  97028.00
> ( rI <- unlist( Ins.Dead[what] ) )</pre>
null.deviance
                     df.null
                                   deviance
                                               df.residual
     4329.880
                   18330.000
                                   3680.391
                                                 18316.000
> ( rA <- unlist( All.Dead[what] ) )</pre>
null.deviance
                     df.null
                                   deviance
                                               df.residual
     24300.15
                   115369.00
                                   21612.94
                                                 115358.00
> round(c(dd \leftarrow rA-(rI+rD), "pVal"=1-pchisq(dd[3],dd[4])), 3)
null.deviance
                     df.null
                                   deviance
                                               df.residual pVal.deviance
       12.314
                       1.000
                                     78.616
                                                     14.000
                                                                     0.000
```

Thus we see there is a substantial non-proportionality of mortality rates from the two states; we shall explore this quantitatively in more detail. Note that the reason that there is a difference in the null deviances (and a difference of 1 in the null d.f.) is that the null deviance of All.Dead refer to a model with a single intercept, that is a model with constant and *identical* mortality rates from the states "DM" and "Ins", whereas the null models for DM.Dead and Ins.Dead have *different* mortality rates from the states "DM" and "Ins". This is however irrelevant for the comparison of the *residual* deviances.

1.4.2 How the mortality rates look

If we want to see how the mortality rates are modelled in DM.Dead and Ins.Dead in relation to All.Dead, we make a prediction of rates for say men diagnosed in different ages and going on insulin at different times after this. So we consider men diagnosed in ages 40, 50, 60 and 70, and who either never enter insulin treatment or do it 1, 3 or 5 years after diagnosis of DM.

So what we do is to create a prediction data frame where we have observation times from diagnosis and 12 years on (longer would not make sense as this is the extent of the data).

We start by setting up an array to hold the predicted mortality rates, classified by diabetes duration, age at onset, time of insulin onset, and of course type of model. What we want to do is to plot the age-specific mortality rates for persons not on insulin, and for person starting insulin at different times after DM. The mortality curves start at the age where the person gets diabetes and continues 12 years.

For convenience we define a function that takes the predicted (log)-rates with s.e.s and converts them to true rates with c.i.:

```
> ci.pred <-
+ function( mod, newdata )
+ {
+ zz <- predict( mod, newdata=newdata, se.fit=TRUE, type="link" )
+ exp( cbind( zz$fit, zz$se.fit ) %*% ci.mat() )
+ }</pre>
```

Then we can set up the prediction data frame and modify it in loops over ages at onset and insulin onset. Note that we set lex.dur to 1000 in the prediction frame, so that we obtain rates in units of events per 1000 PY.

So for each age at DM onset we make a plot of the mortality as function of current age both for those with no insulin treatment at those that start 1, 3 and 5 years after, thus 4 curves (with c.i.). These curves are replicated with a different color for the simplified model.

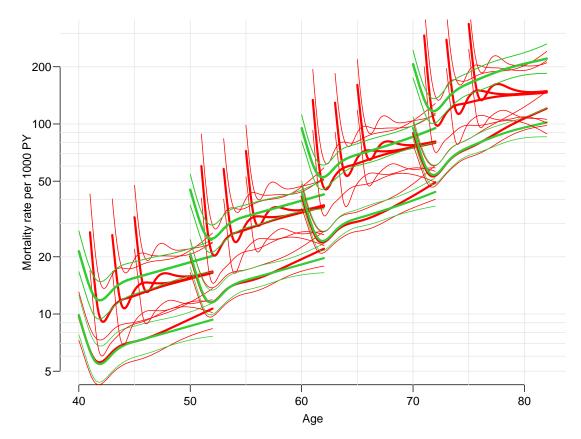

Figure 1.2: Estimated mortality rates for male diabetes patients with no insulin (lower sets of curves) and insulin (upper curves), with DM onset in age 40, 50, 60 and 70. The red curves are from the models with separate age effects for persons with and without insulin, and a separate effect of insulin duration. The green curves are from the model with common age-effects and only a time-dependent insulin effect (the classical time-dependent variable approach).

From figure 1.2 we see that there is a substantial insulin-duration effect which is not accommodated by the simple model with only one time-dependent variable to describe the insulin effect. Note that the simple model (green curves) for those on insulin does not depend in insulin duration, and hence the mortality curves for those on insulin are just parallel to the mortality curves for those not on insulin, regardless of diabetes duration (or age) at the time of insulin initiation. Thus the effect of insulin initiation is under estimated for short duration of insulin and overestimated for long duration of insulin.

This is the major discrepancy between the two models, and illustrates the importance of being able to accommodate different time scales, but there is also a declining overall insulin effect by age which is also overlooked by the proportional hazards approach.

1.5 Input to the simLexis function

In order to simulate from the multistate model with the estimated transition rates, and get the follow-up of a hypothetical cohort, we must supply *both* the transition rates and the structure of the model *as well as* the initial cohort status to simLexis.

1.5.1 The transition object

We first put the models into an object representing the transitions; note this is a list of lists, the latter having glm objects as elements:

Now we have the description of the rates and of the structure of the model. The Tr object defines the states and models for all transitions between them; the object Tr\$A\$B contains the model for the transition intensity from state A to state B.

1.5.2 The initial cohort

> str(Si[NULL,1:9])

We now define an initial Lexis object of persons with all relevant covariates defined. Note that we use subset to get a preLexis object, this conserves the time.scale and time.since attributes which is needed for the simulation (the usual "[" operator does not preserve these attributes when you select columns):

```
Classes 'Lexis' and 'data.frame': 0 obs. of 9 variables:
```

```
Classes 'Lexis' and 'data.frame':
                                             0 obs. of 9 variables:
 $ lex.id : int
        : num
 $ Per
 $ Age
           : num
 $ DMdur : num
 $ t.Ins : num
 $ lex.dur: num
 $ lex.Cst: Factor w/ 4 levels "DM","Ins","Dead",..:
$ lex.Xst: Factor w/ 4 levels "DM","Ins","Dead",..:
 $ sex : Factor w/ 2 levels "M", "F":
 - attr(*, "breaks")=List of 4
  ..$ Per : NULL
  ..$ Age : NULL
  ..$ DMdur: num 0 0.5 1 1.5 2 2.5 3 3.5 4 4.5 ...
  ..$ t.Ins: NULL
 - attr(*, "time.scales")= chr "Per" "Age" "DMdur" "t.Ins"
 - attr(*, "time.since")= chr "" "" "Ins"
```

We now have an empty Lexis object with attributes reflecting the timescales in multistate model we want to simulate, so we must now enter some data to represent the persons whose follow-up we want to simulate through the model:

1.6 Simulation of the follow-up

Now we simulate 5000 of each of these persons using the estimated model. The time.pts argument gives the times at which the integrated intensities (cumulative rates) are evaluated and between which linear interpolation is used when simulating transition times. Note that this must be given in the same units as lex.dur in the Lexis object used for fitting the Poisson models for the transitions.

```

                                     6912
                                              3901
                                                     60920.51
                                                                   5000
```

The result is a Lexis object — a data frame representing the simulated follow-up of 10,000 persons (5000 identical men and 5000 identical women) according to the rates we estimated from the original dataset.

1.6.1 Using different models for simulation

We fitted a proportional mortality model All.Dead (which fitted worse than the other two), this is a model for *both* the transition from "DM" to "Death" *and* from "Ins" to "Dead(Ins)", assuming that they are proportional. But it can easily be used in the simulation set-up, because the state is embedded in the model via the term lex.Cst, which is updated during the simulation.

Simulation using this instead just requires that we supply a different transition object:

```
> Tr.p <- list( "DM" = list( "Ins"
                                         = DM.Ins,
                             "Dead"
                                         = All.Dead
               "Ins" = list( "Dead(Ins)" = All.Dead ) )
 system.time( simL.p <- simLexis( Tr.p,</pre>
                                   ini,
                               t.range = 15,
                                     N = 500 )
        system elapsed
   user
   3.42

Note that in order for this model to be usable for simulation, it is necessary that we use the components of the Lexis object to specify the survival. Each record in the dataframe Si represents follow up from DMdur to DMdur+lex.dur, so the model is a Cox model with diabetes duration as undelying timescale and age at diagnosis as covariate, Age-DMdur.

Also not that we used I(lex.Cst="Ins") instead of just lex.Cst, because coxph assigns design matrix columns to all levels of lex.Cst, also those not present in data, which would give NAs among the parameter estimates and NAs as mortality outcomes.

Alternatively we could have used current age as timescale as underlying time-scale:

```
> Cox.A.Dead <- coxph( Surv( Age, Age+lex.dur,
                              lex.Xst %in% c("Dead(Ins)", "Dead")) ~
                     Ns( Age-DMdur, knots=ad.kn ) +
                     I(lex.Cst=="Ins") +
+
                     I(Per-2000) + sex,
                 data = Si )
 round( ci.exp( Cox.Dead ), 3 )
                                 exp(Est.)
                                             2.5%

We see the choice of time scale makes very little difference in the common parameters.

We see that the effect of insulin and the other covariates are pretty much the same as in the two-time-scale model. We can simulate from this model too; there is no restrictions on what type of model can be used for different transitions

```
> Tr.c <- list( "DM" = list( "Ins"
                                       = Tr$DM$Ins,

                                 14308
                                           7576 119023.93
                        1120
                                                              10000
```

1.7 Reporting the simulation results

We can now tabulate the number of persons in each state at a predefined set of times on a given time scale. Note that in order for this to be sensible, the from argument would normally be equal to the starting time for the simulated individuals.

```
State
           DM Ins Dead Dead(Ins)
when
  1995
         4957 52
                    17
  1995.2 4874 102
                    50
  1995.4 4791 148
                                3
                    84
  1995.6 4717 184
                   116
  1995.8 4638 239
                   138
                               11
  1996 4557 298
                               15
                   156
  1996.2 4487 338
                               19
                    182
                               20
  1996.4 4409 392
                   205
  1996.6 4325 439
                   237
                               25
  1996.8 4246 494
                   255
                               31
```

We see that as time goes by, the 5000 men slowly move away from the starting state (DM). Based on this table (nSt is a table) we can now compute the fractions in each state, or, rather more relevant, the cumulative fraction across the states in some specified order, so that a plot of the stacked probabilities can be made:

```
> pp <- pState( nSt, perm=c(1,2,4,3) )
> head( pp )
when
                DM
                         Ins Dead(Ins) Dead
  1995
         0.9862714 0.9966176 0.9966176
  1995.2 0.9697573 0.9900517 0.9900517
                                          1
  1995.4 0.9532431 0.9826900 0.9832869
  1995.6 0.9385197 0.9751293 0.9769200
                                          1
  1995.8 0.9228014 0.9703542 0.9725428
                                          1
       0.9066852 0.9659769 0.9689614
> par(mfrow=c(1,2), mar=c(3,3,1,1), mgp=c(3,1,0)/1.6)
> plot( pp )
> plot( pp, border="black", col="transparent", lwd=3 )
> text( rep(as.numeric(rownames(pp)[nrow(pp)-1]),ncol(pp)),
        pp[nrow(pp),]-diff(c(0,pp[nrow(pp),]))/3,
        colnames( pp ), adj=1 )
```

A more useful set-up of the graph would include a more through annotation and sensible choice of colors:

```
> clr <- c("limegreen", "orange")</pre>
> # expand with a lighter version of the two chosen colors
> clx <- c( clr, rgb( t( col2rgb( clr[2:1] ) + rep(255,3) ) / 2, max=255 ) )</pre>
> par(mfrow=c(1,2), las=1, mar=c(3,3,4,2), mgp=c(3,1,0)/1.6)
> # Men
> plot( pp, col=clx )
> lines(as.numeric(rownames(pp)), pp[,2], lwd=3 )
> mtext("60 year old male, diagnosed 1990, aged 55", side=3, line=2.5, adj=0, col=gray(0.6) )
> mtext( "Survival curve", side=3, line=1.5, adj=0 )
> mtext( "DM, no insulin DM, Insulin", side=3, line=0.5, adj=0, col=clr[1] )
> mtext( "DM, no insulin", side=3, line=0.5, adj=0, col=clr[2] )
> axis( side=4 )
> # Women
> pf <- pState( nState( subset(simL,sex=="F"),</pre>
                           at = seq(0, 14.8, 0.2),
                           from=1995,
                           time.scale="Per" ),
                  perm = c(1, 2, 4, 3))
> plot( pf, col=clx )
> lines( as.numeric(rownames(pf)), pf[,2], lwd=3 )
> mtext( "60 year old female, diagnosed 1990, aged 55", side=3, line=2.5, adj=0, col=gray(0.6) )
> mtext( "Survival curve", side=3, line=1.5, adj=0 )
> mtext( "DM, no insulin
> mtext( "DM, no insulin DM, Insulin", side=3, line=0.5, adj=0, col=clr[1] )
> mtext( "DM, no insulin", side=3, line=0.5, adj=0, col=clr[2] )
> axis( side=4 )
```

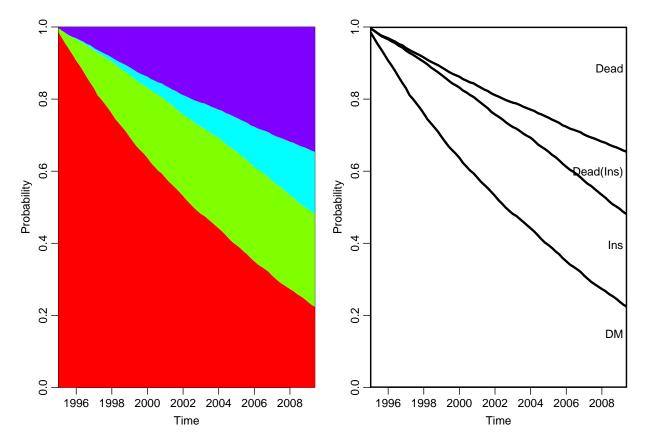

Figure 1.3: Default layout of the plot.pState graph (left), and a version with the state probabilites as lines and annotation of states.

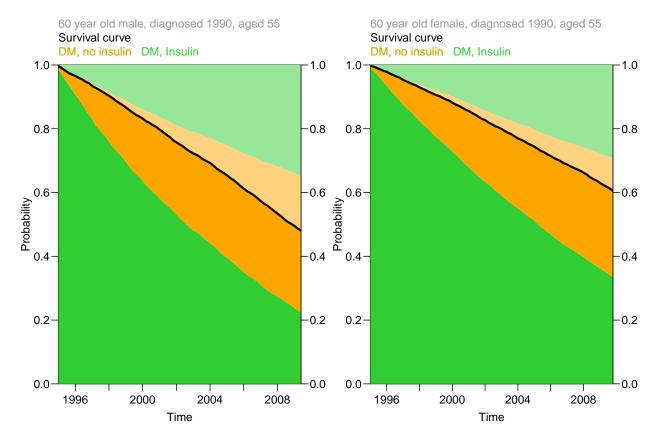

Figure 1.4: plot.pState graphs where persons ever on insulin are given in orange and persons never on insulin in green, and the overall survival (dead over the line) as a black line.

If we instead wanted to show the results on the age-scale, we would just as for that when constructing the probabilities; otherwise the code is pretty much the same as before:

```
> par(mfrow=c(1,2), las=1, mar=c(3,3,4,2), mgp=c(3,1,0)/1.6)
> pm <- pState( nState( subset(simL,sex=="M"),</pre>
                           at = seq(0, 14.8, 0.2),
                            from=60,
                            time.scale="Age" ),
                  perm = c(1, 2, 4, 3))
> plot( pm, col=clx, xlab="Age" )
 lines( as.numeric(rownames(pm)), pm[,2], lwd=3 )
 mtext( "60 year old male, diagnosed 1990, aged 55", side=3, line=2.5, adj=0, col=gray(0.6) )
> mtext( "Survival curve", side=3, line=1.5, adj=0 )
> mtext( "DM, no insulin DM, Insulin", side=3, line=0.5, adj=0, col=clr[1] )
> mtext( "DM, no insulin", side=3, line=0.5, adj=0, col=clr[2] )
> axis( side=4 )
> # Women
> pf <- pState( nState( subset(simL,sex=="F"),</pre>
                           at = seq(0, 14.8, 0.2),
                           from=60,
                            time.scale="Age" ),
                  perm=c(1,2,4,3))
  plot( pf, col=clx, xlab="Age"
 lines(as.numeric(rownames(pf)), pf[,2], lwd=3)
> mtext( "60 year old female, diagnosed 1990, aged 55", side=3, line=2.5, adj=0, col=gray(0.6) )
> mtext( "Survival curve", side=3, line=1.5, adj=0 )
> mtext( "DM, no insulin DM, Insulin", side=3, line=0.5, adj=0, col=clr[1] )
> mtext( "DM, no insulin", side=3, line=0.5, adj=0, col=clr[2] )
> axis( side=4 )
```

1.7.1 Comparing predictions from different models

We have actually fitted different models for the transitions, and we have simulated Lexis objects from both approaches, so we can plot these on top of each other:

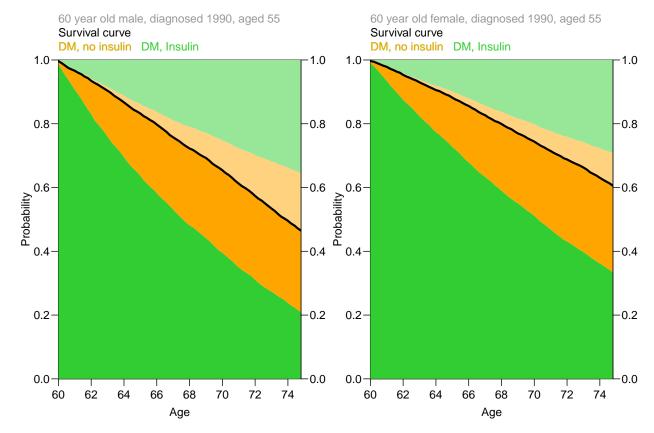

Figure 1.5: plot.pState graphs where persons ever on insulin are given in orange and persons never on insulin in green, and the overall survival (dead over the line) as a black line.

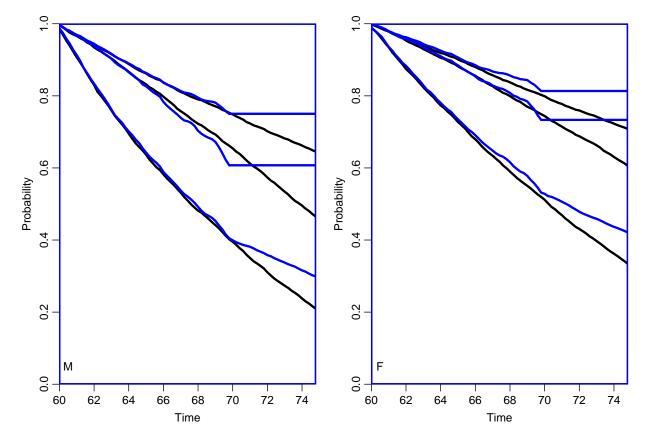

Figure 1.6: Comparison of the simulated state occupancy probabilities using separate Poisson models for the mortality rates with and without indulin (black) and using proportional hazards Cox-models with diabetes duration as timescale and age at diabetes diagnosis as covariate (blue).

Chapter 2

Simulation of transition times

2.1 Theory

Suppose that the rate functions for the transitions out of the current state to, say, 3 different states are λ_1 , λ_2 and λ_3 , and the corresponding cumulative rates are Λ_1 , Λ_2 and Λ_3 , and we want to simulate an exit time and an exit state (that is either 1, 2 or 3). This can be done in two slightly different ways:

- 1. First time, then state:
 - (a) Compute the survival function, $S(t) = \exp(-\Lambda_1(t) \Lambda_2(t) \Lambda_3(t))$
 - (b) Simulate a random U(0,1) variate, u, say.
 - (c) The simulated exit time is then the solution t_u to the equation $S(t_u) = u \iff \sum_j \Lambda_j(t_u) = -\log(u)$.
 - (d) A simulated transition at t_u is then found by simulating from the multinomial distribution with probabilities $p_i = \lambda_i(t_u) / \sum_j \lambda_j(t_u)$.
- 2. Separate cumulative incidences
 - (a) Simulate 3 independent U(0,1) random variates u_1 , u_2 and u_3 .
 - (b) Solve the equations $\Lambda_i(t_i) = -\log(u_i), i = 1, 2, 3$ and get (t_1, t_2, t_3) .
 - (c) The simulated survival time is then $\min(t_1, t_2, t_3)$, and the simulated transition is to the state corresponding to this, that is $k \in \{1, 2, 3\}$, where $t_k = \min(t_1, t_2, t_3)$

The intuitive argument is that with three possible transition there are 3 independent processes running, but only the first transition is observed. The latter approach is used in this implementation.

The formal argument for the equality of the two approaches goes as follows:

- 1. Equality of the transition times:
 - (a) In the first approach we simulate from a distribution with cumulative rate $\Lambda_1(t) + \Lambda_2(t) + \Lambda_3(t)$, hence from a distribution with survival function:

$$S(t) = \exp(-(\Lambda_1(t) + \Lambda_2(t) + \Lambda_3(t)))$$

= $\exp(-\Lambda_1(t)) \times \exp(-\Lambda_2(t)) \times \exp(-\Lambda_3(t))$

(b) In the second approach we choose the smallest of three survival times, each with survival function $\exp(-\Lambda_i)$, i = 1, 2, 3. Now, the survival function for the minimum of three survival times is:

$$S_{\min}(t) = P \{ \min(t_1, t_2, t_3) > t \}$$

= $P \{t_1 > t\} \times P \{t_2 > t\} \times P \{t_3 > t\}$
= $\exp(-\Lambda_1(t)) \times \exp(-\Lambda_2(t)) \times \exp(-\Lambda_3(t))$

which is the same survival function as derived above.

2. Type of transition:

- (a) In the first instance the conditional distribution of the state to which the transition is, conditional on the transition time being t, is taken as: $\lambda_i(t)/(\lambda_1(t) + \lambda_2(t) + \lambda_3(t))$.
- (b) In the second approach we choose the transition corresponding to the the smallest of the transition times. So when we condition on the event that a transition takes place at time t, we have to shown that the conditional probability that the smallest of the three simulated transition times was actually the ith, is as above.

But the probabilities conditional on *survival* till t, that events of type 1, 2, 3 takes place in the interval (t, t + dt) are $\lambda_1(t) dt$, $\lambda_2(t) dt$ and $\lambda_1(t) dt$, respectively, hence the conditional probabilities *given a transition time* in (t, t + dt) is exactly a above:

$$\frac{\lambda_i(t) dt}{\lambda_1(t) dt + \lambda_2(t) dt + \lambda_3(t) dt} = \frac{\lambda_i(t)}{\lambda_1(t) + \lambda_2(t) + \lambda_3(t)}$$

2.2 Components of simLexis

This section explains the actually existing code for simLexis, as it is in the current version of Epi. The function simLexis takes a (pre-)Lexis object as input. This defines the initial state(s) and times of the start for a number of persons. Since the purpose is to simulate a history through the estimated multistate model, the input values of the outcome variables lex.Xst and lex.dur are ignored — the aim is to simulate values for them.

Note however that the attribute time.since must be present in the object. This is used for initializing timescales defined as time since entry into a particular state, it is a character vector of the same length as the time.scales attribute, with value equal to a state name if the corresponding time scale is defined as time since entry into that state. In this example the 4th timescale is time since entry into the "Ins" state, and hence:

Lexis objects will have this attribute set for time scales created using cutLexis.

The other necessary argument is a transition object Tr, which is a list of lists. The elements of the lists should be glm objects derived by fitting Poisson models to a Lexis object representing follow-up data in a multistate model. It is assumed (but not checked) that timescales enter in the model via the timescales of the Lexis object. Formally, there are no assumptions about how lex.dur enters in the model.

The two optional arguments are time.pts, a numerical vector giving the times after entry at which the cumulative rates will be computed (the maximum of which will be taken as the censoring time), and N a scalar or numerical vector of the number of persons with a given initial state each record of the init object should represent.

The central part of the functions uses a do.call / lapply / split construction to do simulations for different initial states. This is the construction in the middle that calls simX. simLexis also calls get.next which is also detailed below.

> simLexis

```
function( Tr, # List of lists of transition objects
        init, # Lexis object of persons to simulate.
           N = 1, # No. persons simulated per line in init
     t.range = 20, # Range for rate computation in the simulation
       n.int = 101, # length of time intervals
    time.pts = seq(0,t.range,length.out=n.int)
\mbox{\#}\xspace Expand the input data frame using N and put in lex.id
if( time.pts[1] !=0 )
    stop( "First time point must be 0, time.pts[1:3] = ",
          time.pts[1:3])
# Expand init
if( !missing(N) )
  if(length(N) == 1)
       init <- init[rep(1:nrow(init),each=N),]</pre>
  else init <- init[rep(1:nrow(init),</pre>
# and update lex.id if necessary
if( !missing(lex.id) )
  if( length(lex.id) == nrow(init) )
       init$lex.id <- lex.id</pre>
  else init$lex.id <- 1:nrow(init)</pre>
  }
      init$lex.id <- 1:nrow(init)</pre>
else
# Check/fix attributes
if( is.null( tS <- attr(init, "time.scales") ) )</pre>
  stop( "No time.scales attribute for init" )
if( is.null( tF <- attr(init, "time.since") ) )</pre>
  attr(init, "time.since") <- tF <- rep( "", tS )
  warning( "'time.since' attribute set to blanks" )
# Convenience constants
np <- length( time.pts )</pre>
tr.st <- names( Tr )
# Set up a NULL object to hold the follow-up records
sf <- NULL
```

```
# Take only those who start in a transient state
nxt <- init[init$lex.Cst %in% tr.st,]</pre>
# If some are not in a transient state then say so
if( nrow(nxt) < nrow(init) )</pre>
  tt <- table(init$lex.Cst)</pre>
  tt <- tt[tt>0]
  nt <- length(tt)</pre>
  warning("\nSome initiators start in a absorbing state\n",
           "Initiator states represented are: ",
           if( nrow(nxt)==0 ) stop( "\nNo initiators in transient states!" )
# Then we update those who are in a transient states and keep on doing
# that till all are in absorbing states or censored
while( nrow(nxt) > 0 )
nx <- do.call( "rbind",</pre>
                lapply( split( nxt,
                                 nxt$lex.Cst ),
                         simX.
                         Tr, time.pts, tS ) )
sf <- rbind( sf, nx )</pre>
nxt <- get.next( nx, tr.st, tS, tF )</pre>
# Doctor lex.Xst levels, fix values for the censored
sf$lex.Xst <- factor( sf$lex.Xst, levels=levels(sf$lex.Cst) )</pre>
sf$lex.Xst[is.na(sf$lex.Xst)] <- sf$lex.Cst[is.na(sf$lex.Xst)]
# Nicely order the output by persons, then times and states
nord <- match( c( "lex.id", ts,</pre>
                    "lex.dur",
                    "lex.Cst"
                    "lex.Xst" ), names(sf) )
noth <- setdiff( 1:ncol(sf), nord )
sf <- sf[order(sf$lex.id,sf[,tS[1]]),c(nord,noth)]</pre>
rownames(sf) <- NULL
# Finally, supply attributes
attr( sf, "time.scales" ) <- tS
attr( sf, "time.since" ) <- tF</pre>
chop.lex( sf, tS, max(time.pts) )
<environment: namespace:Epi>
```

2.2.1 simX

simX simulates transition-times and -types for a set of patients assumed to be in the same state. It is called from simLexis with a data frame as argument, uses the state in lex.Cst to select the relevant component of Tr and compute predicted cumulative intensities for all states reachable from this state.

Note that it is here the switch between glm, coxph and objects of class function is made. The dataset on which this prediction is done has length(time.pts) rows per person.

```
function( nd, Tr, time.pts, tS )
# Simulation is done from the data frame nd, in chunks of starting
# state, lex.Cst. This is necessary because different states have
# different (sets of) exit rates. Therefore, this function simulates
# for a set of persons from the same starting state.
np <- length( time.pts )</pre>
nr <- nrow( nd )
if( nr==0 ) return( NULL )
# The 'as.character' below is necessary because indexing by a factor
# by default is by the number of the level, and we are not indexing by
# this, but by components of Tr which just happens to have names that
# are a subset of the levels of lex.Cst.
cst <- as.character( unique(nd$lex.Cst) )</pre>
if( length(cst)>1 ) stop( "More than one lex.Cst present:\n", cst, "\n" )
# Expand each person by the time points
prfrm <- nd[rep(1:nr,each=np),]</pre>
prfrm[,tS] <- prfrm[,tS] + rep(time.pts,nr)
prfrm$lex.dur <- il <- min( diff(time.pts) )</pre>
# Poisson-models shoull use the estimated rate at the midpoint of the
# intervals:
prfrp <- prfrm
prfrp[,tS] <- prfrp[,tS]+i1/2</pre>
# Make a data frame with predicted rates for each of the transitions
# out of this state for these times
rt <- data.frame( lex.id = prfrm$lex.id )</pre>
for( i in 1:length(Tr[[cst]]) )
   if( inherits( Tr[[cst]][[i]], "glm" ) )
   rt <- cbind( rt, predict( Tr[[cst]][[i]],
                               type="response"
                               newdata=prfrp ) )
   else
   if( inherits( Tr[[cst]][[i]], "coxph" ) )
   rt <- cbind( rt, predict( Tr[[cst]][[i]],</pre>
                               type="expected"
                               newdata=prfrm ) )
   if( is.function( Tr[[cst]][[i]] ) )
   rt <- cbind( rt, Tr[[cst]][[i]](prfrm) )</pre>
   else
   stop( "Invalid object supplied as transition, must be either\n",
          'glm(poisson) or coxph object fitted to a Lexis object or\n",
          "a function that takes a Lexis object as argument and returns\n",
          "average rates for each record in the same units as lex.dur.")
   }
names( rt )[-1] <- names( Tr[[cst]] )</pre>
# Then find the transition time and exit state for each person:
xx <- match( c("lex.dur","lex.Xst"), names(nd) )</pre>
if( any(!is.na(xx)) ) nd <- nd[,-xx[!is.na(xx)]]</pre>
merge( nd,
       do.call( "rbind",
                  lapply( split( rt,
                                  rt$lex.id),
                          sim1,
                          time.pts ) ),
       by="lex.id" )
<environment: namespace:Epi>
```

simX calls sim1 which simulates the transition for one person.

2.2.2 sim1

The predicted cumulative intensities are fed, person by person, to sim1 — again via a do.call / lapply / split construction — and the resulting time and state is appended to the nd data frame. This way we have simulated *one* transition for each person:

```
> Epi:::sim1
function( rt, time.pts )
# Simulates a single transition time and state based on the data frame
# rt with columns lex.id and timescales. The rows in rt are the id,
# followed by the set of estimated transition rates to the different
# states reachable from the current one.
ci <- apply( rt[,-1,drop=FALSE], 2, cumsum )</pre>
tt <- uu <- -log( runif(ncol(ci)) )
for( i in 1:ncol(ci) ) tt[i] <- lint( ci[,i], time.pts, uu[i] )</pre>
# Note this resulting data frame has 1 row
data.frame(lex.id = rt[1,1],
            lex.dur = min(tt,na.rm=TRUE),
            lex.Xst = factor( if( min(tt) < max(time.pts) )</pre>
                                   colnames(ci)[tt==min(tt)]
                               else NA ) )
<environment: namespace:Epi>
```

2.2.3 lint

Note that we do not use approx to do linear interpolation, because this function does not do the right thing if the cumulative incidences (ci) are constant across a number of times. Hence we have a custom made linear interpolator that does the interpolation exploiting the fact the the ci is non-decreasing and tt is monotonely increasing:

```
function( ci, tt, u )
{
    # Makes a linear interpolation, but does not crash if all ci values are
    # identical, but requires that both ci and tt are non-decreasing
    if( any( diff(ci)<0 ) | any( diff(tt)<0 ) ) stop("Non-icreasing arguments")
    c.u <- min( c( ci[ci>u], max(ci) ) )
    c.l <- max( c( ci[ci<u], min(ci) ) )
    t.u <- min( c( tt[ci>u], max(tt) ) )
    t.l <- max( c( tt[ci<u], min(tt) ) )
# c.u==c.l if u is outside the range of ci
    ifelse( c.u==c.l, t.l, t.l + (u-c.l)/(c.u-c.l)*(t.u-t.l) )
} <-nvironment: namespace:Epi>
```

2.2.4 get.next

We must repeat this operation on those that have a simulated entry to a transient state, and also make sure that any time scales defined as time since entry to one of these states be initialized to 0 before a call to simX is made for these persons. This accomplished by the function get.next:

```
> Epi:::get.next
function( sf, tr.st, tS, tF )
# Produces an initial Lexis object for the next simulation for those
# who have ended up in a transient state.
# Note that this exploits the existence of the "time.since" attribute
# for Lexis objects and assumes that a character vector naming the
# transient states is supplied as argument.
if( nrow(sf)==0 ) return( sf )
nxt <- sf[sf$lex.Xst %in% tr.st,]</pre>
if( nrow(nxt) == 0 ) return( nxt )
nxt[,tS] <- nxt[,tS] + nxt$lex.dur</pre>
wh <- tF
for( i in 1:length(wh) )
   if( wh[i] != "" ) nxt[nxt$lex.Xst==wh[i],tS[i]] <- 0</pre>
nxt$lex.Cst <- nxt$lex.Xst</pre>
return( nxt )
<environment: namespace:Epi>
```

2.2.5 chop.lex

The operation so far has censored individuals max(time.pts) after each new entry to a transient state. In order to groom the output data we use chop.lex to censor all persons at the same designated time after initial entry.

```
> Epi:::chop.lex
function( obj, tS, cens )
# A function that chops off all follow-up beyond cens since entry for
# each individual
# Entry times on 1st timescale
zz <- entry( obj, 1, by.id=TRUE )</pre>
# Merge with the revised exit times on this timescale
ww <- merge( obj, data.frame( lex.id = as.numeric(names(zz)),</pre>
                                  cens = zz+cens ) )
# Only retain records with an entry time prior to the revised exit time
ww <- ww[ww[,tS[1]] < ww$cens,]
\ensuremath{\mathtt{\#}} Revise the duration according the the revised exit time
x.dur <- pmin( ww$lex.dur, ww[,"cens"]-ww[,tS[1]] )</pre>
# Change lex. Xst to lex. Cst for those with shortened follow-up
ww$lex.Xst[x.dur<ww$lex.dur] <- ww$lex.Cst[x.dur<ww$lex.dur]
# Insert the updated follow-yp time
ww$lex.dur <- pmin( x.dur, ww$lex.dur )</pre>
<environment: namespace:Epi>
```

2.3 Probabilities from simulated Lexis objects

Once we have simulated a Lexis object we will of course want to use it for estimating probabilities, so basically we will want to enumerate the number of persons in each state at a pre-specified set of time points.

2.3.1 nState

Since we are dealing with multistate model with potentially multiple time scales, it is necessary to define the timescale (time.scale), the starting point on this timescale (from) and the points after this where we compute the number of occupants in each state, (at).

> nState

```
function (obj,
           at,
         from,
    time.scale = 1 )
{
# Counts the number of persons in each state of the Lexis object 'obj'
# at the times 'at' from the time 'from' in the time scale
# 'time.scale'
# Determine timescales and absorbing and transient states
tS <- Epi:::check.time.scale(obj,time.scale)
TT <- tmat(obj)
absorb <- rownames(TT)[apply(!is.na(TT),1,sum)==0]</pre>
transient <- setdiff( rownames(TT), absorb )</pre>
# Expand each record length(at) times
# Stick in the corresponding times on the chosen time scale
tab.frm$when <- rep( at, nrow(obj) ) + from
# For transient states keep records that includes these points in time
tab.tr <- tab.frm[tab.frm[,tS]
                                            <= tab.frm$when &</pre>
                 tab.frm[,tS]+tab.frm$lex.dur > tab.frm$when,]
tab.tr$State <- tab.tr$lex.Cst</pre>
# For absorbing states keep records where follow-up ended before
tab.ab <- tab.frm[tab.frm[,tS]+tab.frm$lex.dur <= tab.frm$when &
                 tab.frm$lex.Xst %in% absorb,]
tab.ab$State <- tab.ab$lex.Xst</pre>
# Make a table using the combination of those in transient and
# absorbing states.
with( rbind( tab.ab, tab.tr ), table( when, State ) )
<environment: namespace:Epi>
```

2.3.2 pState, plot.pState and lines.pState

In order to plot probabilities of state-occupancy it is useful to compute cumulative probabilities across states in any given order; this is done by the function pState:

> pState

```
function( nSt, perm=1:ncol(nSt) )
{
# Compute cumulative proportions of persons across states in order
# designate by 'perm'
tt <- t( apply( nSt[,perm], 1, cumsum ) )
tt <- sweep( tt, 1, tt[,ncol(tt)], "/" )
class( tt ) <- c("pState", "matrix")
tt
}
<environment: namespace:Epi>
```

There is also a plot and lines method for the resulting pState objects:

```
> plot.pState
function(x,
        col = rainbow(ncol(x)),
     border = "transparent",
       xlab = "Time",
       ylim = 0:1,
       ylab = "Probability", ...)
# Function to plot cumulative probabilities along the time scale.
matplot( as.numeric(rownames(x)), x, type="n",
         ylim=ylim, yaxs="i", xaxs="i",
         xlab=xlab, ylab=ylab, ...)
lines.pState( x,
        col = col
     border = border, ... )
<environment: namespace:Epi>
> lines.pState
function(x,
        col = rainbow(ncol(x)),
     border = "transparent", ... )
# Function to plot cumulative probabilities along the time scale.
# Fixing the colors:
nc <- ncol(x)
col <- rep( col , nc )[1:nc]
border <- rep( border, nc )[1:nc]
# Just for coding convenience when plotting polygons
pSt <- cbind(0, x)
for( i in 2:ncol(pSt) )
                 as.numeric(rownames(pSt))
   polygon( c(
              rev(as.numeric(rownames(pSt)))),
             c( pSt[,i ],
              rev(pSt[,i-1])),
             col=col[i-1], border=border[i-1], ...)
   }
}
<environment: namespace:Epi>
```
